Abstract

Changes in the observed size- or age-composition of commercial catch can occur for a variety of reasons including: market demand, availability, temporal changes in growth, time-area closures, regulations, or change in fishing practice, to name but a few. Two common approaches for dealing with time-varying selectivity in assessment models are the use of discrete time-blocks associated with an epoch in the history of the fishery, or the use of penalized random walk models for parametric or non-parametric selectivity curves. Time block periods, or penalty weights associated with time-varying selectivity parameters, are subjective and often developed on an ad hoc basis. A factorial simulation-estimation experiment, with discrete or continuous changes in selectivity, is conducted to determine the best practices for modeling time-varying selectivity in fisheries stock assessments. Both the statistical properties of the assessment model and the policy implications of choosing the wrong model are taken into consideration.

Introduction

There are many reasons why fisheries selectivity may vary over time and the impact of ignoring changes in selectivity in age- or size-structured stock assessment models leads to biased estimates of abundance and mortality rates. Moreover, not accounting for changes in selectivity can lead to extremely optimistic projections in stock abundance (e.g., 2J3KL cod stocks, Walters and Maguire, 1996).

Currently there are two general approaches for incorporating time-varying selectivity in stock assessment models; 1) the use of discrete time-blocks, and 2) continuous penalized random walk approach. The use of discrete time-blocks should be done *a priori*, where the specified time blocks represent periods consistent fishing practice, and a new block is specified when significant changes in fishing practice occur that may result in changes in selectivity. In practice, however, the time-blocks are also implemented *post hoc* to justify residual patterns in age- or size-composition data. To some, this practice seems rather subjective, and it

is. Another discrete approach is to decompose the fisheries catch statistics into specific time periods that correspond to major transitions in fishing practice. For example, the BC herring fishery prior to 1970 was largely a reduction fishery where herring were harvested during the winter months using purse seines. After the collapse of the fishery in 1969, the fishery re-opened as a gill-net fishery targeting older sexually mature female herring for valuable roe. This change in fishing practice led to a significant change in the selectivity of the fishing gear.

The alternative approach is to allow for continuous changes in selectivity and model estimated selectivity parameters as a penalized random walk. In this case, specification of the variance parameter in how quickly selectivity is allowed to change is also somewhat subjective. It should also be noted that the choice of a time-invariant selectivity is also a subjective structural assumption of the assessment model, and this choice can also greatly influence model results, estimates of reference points, and result in bias forecasts.

Changes in fisheries selectivity also has implications for reference points based on maximum sustainable yield (MSY, Beverton and Holt, 1993). Trends towards catching smaller fish result in reductions in the harvest rate that would achieve MSY; therefore, it is important to account for changes in selectivity (and the associated uncertainty) when developing harvest policy for any given stock.

The over-arching objective is to determine if it is safer to assume more structural complexity in selectivity when the data are in fact simple and is it safer to assume simple structural complexity in selectivity when the data come from a fishery with dynamic changes in selectivity. In this paper, we conduct a series of simulation experiments using a factorial design with fixed selectivity, discrete changes in selectivity, and continuous changes in selectivity and compare statistical fit, retrospective bias, and estimated policy parameters using simulated data. We also explore the use of two-dimensional interpolation methods to reduce the number of estimated latent variables when selectivity is assumed to vary over time.

Methods

Data were generated from an age-structured assessment model based on the Pacific hake assessment conducted at the end of the 2009 fishing season. Simulate data were based on 3 alternative scenarios that assumes selectivity is (1) constant over time, (2) selectivity changes at 3 specific blocked time-periods, and (3) that selectivity changes continuously over time where the commercial fishery targets abundant cohorts over time. First we describe the model structure used to simulate data and estimate model parameters, followed by a description of the MSY-based reference points, and lastly the detailed description of the various scenario combinations explored.

Model description

The same statistical catch-age model was used to both generate simulated data sets and estimate model parameters. The simulation-estimation experiments were based on the Pacific

hake fishery from 1977 to 2009, using the historical catch time series from US and Canada combined and the empirical weight-at-age data from this fishery (Martell, 2009). The model was written in AD Model Builder (Fournier et al., 2011) and all model code and data are available from a code repository (see CAPAM branch at `https://github.com/smartell/iSCAM`).

Input data for the model consist of historical removals along with age-composition information and empirical weight-at-age data from the commercial fishery. Fisheries independent survey information includes an index of abundance based on a systematic coast wide acoustic survey and age-composition information. The actual acoustic survey for Pacific hake historically occurred every 3 years prior to 1995, then every two years, and since 2011 has occurred every year. For our purposes we assumed an annual abundance index is available for each and every year between 1977 and 2009.

Simulation-estimation experiments were based on the maximum likelihood estimates of the initial numbers-at-age and annual recruitment deviations based on fitting the model to the true Pacific hake data. In simulating data, a unique random number seed was used to ensure observation errors in the survey and catch-at-age sampling under alternative hypotheses about the commercial selectivity were repeatable. Initial and annual recruitment deviates were fixed at the maximum likelihood estimates from the real Pacific hake data for all simulations. The annual relative abundance data was assumed to be proportional to the available biomass and to have log-normal measurement errors:

$$I_t = q e^{\sigma_1 \epsilon_t - 0.5 \sigma_1^2} \sum_a \nu_a N_{a,t} W_a \tag{1}$$

where the random deviate is $\epsilon \sim N(0,1)$, σ is the standard error, ν_a is the age-specific proportion that this selected by the acoustic sampling gear, $N_{a,t}$ is the numbers-at-age, and W_a is the average weight-at-age during the survey.

Age-composition data for both commercial and acoustic surveys were based on random samples from a multivariate distribution with a probability of $p_{a,t}$ of sampling a fish of a given age in a given year. The age-proportion samples must sum to 1 in each year, and random samples were based on the the following:

$$x_{a,t} = \ln(\hat{p}_{a,t}) + \sigma_2 \epsilon_{a,t} - \frac{1}{A} \left[\sum_a \ln(\hat{p}_{a,t}) + \sigma_2 \epsilon_{a,t} \right],$$

$$p_{a,t} = \frac{e^{x_{a,t}}}{\sum_a e^{x_{a,t}}} \tag{2}$$

where $\epsilon_{a,t}$ is a standard random normal deviate, σ_2 is the standard error, $\hat{p}$ is the expectation of the proportion-at-age in year t in the sampled catch.

True parameter values used in the simulation model are listed in Table 1. Annual fishing mortality rates were conditioned on the observed catch from the Pacific hake fishery and it was assumed that both natural mortality and fishing mortality occur simultaneously. Simulated age-specific fishing mortality rates were based on the annual age-specific selectivity which differs among three alternative simulation scenarios (see description in the Scenarios subsection).

Table 1: Parameters used for simulation model in the integrated statistical catch-age model.

Description	Symbol	Value
Unfished age-1 recruits	R_o	3.353
Steepness (Beverton-Holt)	h	0.727
Natural mortality rate	M	0.230
Average age-1 recruitment	$\bar{R}$	1.300
Initial recruitment	$\dot{R}$	0.428
Survey standard deviation	σ_1	0.200
Standard deviation in recruitment	σ_R	1.120
Age at 50% selectivity in survey	$\hat{a}$	2.500
Std in 50% selectivity in survey	$\hat{g}$	0.500
Std in age-sampling error	σ_2	0.200

Parameter estimation

Model parameters were estimated using maximum likelihood methods where the objective function includes additional penalties to constrain the shape of the selectivity curve and how much its allowed to vary over time. There are 6 major components to the objective function that is being minimized: (1) the likelihood of the observed catch (T2.5), (2) the likelihood of the relative abundance index (T2.6), (3) the likelihood of the age-composition information (T2.7), (4) the likelihood of the stock-recruitment data to estimate steepness and unfished age-1 recruits (T2.8), (5) prior densities in negative log space for estimated model parameters(T2.9), and (6) penalties and constraints for selectivity coefficients (T2.10).

The observed catch data are assumed to have a lognormal error structure and the standard deviation in the residuals between observed and predicted log catch is fixed at 0.0707 for all years. The likelihood for the relative abundance data is assumed to have lognormal errors and the assumed standard deviation in the residuals is fixed at 0.20. Note that the conditional maximum likelihood estimate for q is used in the likelihood calculation (Walters and Ludwig, 1994), and we use a weak informative prior of $\ln(q) \sim N(0, 0.75)$ for the derived value of q in our simulation studies to stabilize the scaling parameters in Monte Carlo trials. Test with this weak informative prior and a uniform prior on the true Pacific hake data yielded identical MLE estimates.

The likelihood for age-composition information collected from commercial fisheries and the fisheries independent survey was assumed to come from a multivariate logistic distribution, and these data were weighted by the conditional maximum likelihood of the variance. Residual difference between observed and predicted age-proportions were calculated using (T2.3) with the constraint that $\sum_a \eta_{a,t} = 0$. The advantage of this approach over a multinomial likelihood with a fixed effective sample size, is that the age-composition data are weigthed appropriately conditional on the model structure (Schnute and Richards, 1995). An important point to note about the calculation of the age-composition residuals in (T2.3)

4

is that many others will add a small constant to both the observed and predicted proportion-at-age to avoid taking the logarithm of a 0 observation. In cases where year-classes are extremely weak and only partially selected by the fishing gear, the assumed value of the constant can influence the overall result. To avoid this problem, we alter the definition of an age-class in years where the osberved proportion-at-age is 0 and pool this cohort into the adjacent age-class. In our simulation testing, this grouping of age classes was much more robust for parameter estimation and did not appear to produce any significant biases in comparison to methods that just add a small constant. Similar results were also obtained by Richards et al. (1997).

Annual age-1 recruitment was estimated via a mean recruitment value and a vector of deviates that were constrained to sum to 0. The integtrated statistical catch age-model also jointly estimates the parameters of the resulting stock recruitment relationship given estiamtes of annual age-1 recruits and the resutling spawning stock biomass. Residual deviations between annual recruitment and recruitment based on a Beverton-Holt stock recruitment model were calculated using (T2.4), and the unfished age-1 recruits (R_o) and steepness paraemters (h) were jointly estimated based on the negative loglikelihood (T2.8).

Uniform priors were assumed for all the leading parameters with the exception of an informative beta distribution for the steepness parameter in the interval 0.2–1.0. The expected value for the steepness prior was set at 0.6 with a standard deviation of 0.161.

Note that in (T2.10) there are three terms, the first of which is a penalty on the second differences between the age-specific coefficients to ensure a smooth ascending–descending pattern. The second term is a penalty on the amount of dome-shaped selectivity (often necessary when jointly estimating natural mortality rates). The third term is a second difference penalty on how age-specific coefficients vary over time. In each case the user must specify the relative weights λ that each of these penalties. For example, and infinitely large value of $\lambda^{(3)}$ would imply that selectivity coefficients are invariant over time.

Reference points

Reference points based on long-term maximum sustainable yield (MSY-based reference points) were calculated assuming steady-state conditions. It was assumed that removals from the fishery independent survey were negligible. The fishing mortality rate that produced the maximum sustainable yield was determined by setting the derivative of the catch equation to 0 and solving for F_{MSY}. MSY was was subsequently determined by calculating the steady-state catch using F_{MSY}. Similarly B_{MSY} was determined by calculating the steady-state spawning biomass under a fishing mortality rate of F_{MSY}. Detailed descriptions of the steady state calculations for MSY-based reference points can be found in Martell et al. (2008).

All MSY-based reference points were based on the estimated selectivity value in the terminal year of the assessment. In cases where selectivity is assumed to remain constant over time, the estimated MSY-based reference points vary with minor updates to population parameters as the time series increases in length. However in cases where selectivity is
Figure 1: True selectivity curves used to generate simulated data sets for scenario 1 (left), scenario 2 (middle), scenario 3 (right).

assumed to vary over time, MSY-based reference points become highly uncertain as the uncertainty in selectivity in the terminal year is a function of how much selectivity is allowed to vary.

Scenarios

Three alternative datasets were generated with the simulation model using: (1) fixed age-based selectivity based on an asymptotic logisitic funciton, (2) three time blocks where an asymptotic function changes in 1985 and 1996, and (3) continous changes in selectivity each year where the fishery targets cohorts based on Ideal Free Distribution (IFD). For the IFD selectivity model, the age-speific selectivity coefficients were based on age-specific biomass that is vulnerable to the fishing gear. Given a vector of selectivity coefficients v_a (based on the same logistic function used in the other scenarios), the age-specific selectivity coefficients each year were based on the relative biomass-at-age b_a in a given year, and rescaled such that the mean of the vector is equal to 0 in log-space:

$$\omega_a = \ln(v_a) + 0.25\ln(b_a) - \frac{1}{A}\sum_{a=1}^{A}[\ln(v_a) + 0.25\ln(b_a)] \tag{3}$$

The coefficient of 0.25 is an arbitrary scaling of the biomass-at-age that would relate price premiums to larger size fish. The larger the price premium the less dome-shaped the selectivity curve would be because there is a financial incentive to target larger more valuable fish. In anycase, the unique feature of (3) is that it allows for modal and multi-modal selectivity curves based on the relative abundance of each cohort (Figure 1).

Four altnerative selectivity states were assumed in the assessment model (denoted by a-d). For the fixed scenario, we assumed that selectivity was constant over time, and estimated

6

7 selectivity coefficients (or knots) equally spaced starting at age-1 and ending at age-15 and interpolated between these knots using a cubic spline function. An additional penalty was added to the objective function to ensure smooth changes between ages and limit the amount of dome-shaped in the selectivity coefficients; values for $\lambda^{(1)}$ and $\lambda^{(2)}$ were both set at 12.5 which is roughly equivalent to a 20% coefficient of variation.

The same selectivity penalty weights were also applied to model (b), which estimates the same 7 spline knots for three distinct time blocks separted between 1985 and 1996. In this case there are a total of 21 selectivit coeffients being estimated. Here we assume the timing of the discrete changes in selectivity corresponds to some known event and the years in which selectivity changes was correctly specified.

For model (c) the same penalized 7 spline knots are estimated for each year for a total of 231 selectivity parameters. An additional penalty weight of $\lambda^{(3)} = 1.0$ was added to the time varying selectivity option to constrain (with a CV=0.707) how rapidly age-specific selectivity coefficients can change over time. Near identical results were also obtained with $\lambda^{(3)} = 0.0$, but parameter estimation convergence in Monte Carlo trials was less likely under no weight.

An altnerative to the annual time-varying selectivity is to interpolate in 2-dimensions where a series of knots for both age and year are treated as the estiamted parameters, and the age-year selectvity coefficients are interpolated using a bicubic spline. For comparison with model (c), model (d) is based on estiamting 7-age based knots and 12-time based knots for a total of 84 estimated selectivity patterns. In this case the same penalty weights are assumed for smoothing, dome-shaped and time-varying changes in age-based selectivity as that used for model (c).

We examine three criterion for choosing the appropriate selectivity parameterization, taking into consideration that the appropriate structural assumption may not be known. The first criterion compares how well each model configuration explains simulated data (statistical fit), examines the root mean square errors of the residuals, and uses Akaike Information Criterion as a basis for contrasting overall performance. Retrospective performance is the second criterion we examine, as retrospective biases in stock assessments can potentially lead to severe over-exploitation, or under utilization of the resources depending on the direction of bias. Finally, we examine the performance of estimatining reference points using Monte Carlo trials.

Results

Statisical fit

Statisitics summarizing how well each model fits a single realization of simulated data is based on the overall objective function value (i.e., the negative loglikelihood in Table 4), Akaike Information Criterion (AIC) and the Root Mean Square Error (RMSE) for survey index residuals, recruitment deviations and age-composition data from both commercial and survey samples (Table 4). Under conditions in which the true selectivity does not change over

time, similar fits to the relative abundance index (see Survey RMSE in Table 4) are obtained regardless if survey selectivity was assumed to be constant or varies over time. Allowing for additional structure in the selectivity coefficients over time resulted in decreases in the RMSE from 0.186 to 0.314 for the commercial age-composition information.

We do not recommend using model selection criterion such as AIC to choose the most appropriate model; however, we provide AIC and ΔAIC values to give a sense of the relative differences between the various assessment models for each simulation case. In the cases examined here (Table 4, AIC always favors the most structurally complex model (model c) with the largest number of estimated selectivity parameters. Model c also always results in over-fitting the age-composition information; the RMSE values for the commercial age-composition data were significantly less than the true value of 0.2 used in generating the age-composition data. In scenario 1a (simulated and assumed fixed selectivity), the RMSE values for the residuals are nearest the values used to simulate the observation errors in the survey and age-composition data.

In the case where the true selectivity changes discretely over three time blocks, assessment models with time-varying selectivity (c) and (d) appear to fit the data better that models that assumed fixed selectivity (a), or even the discrete changes in selectivity (see ΔAIC values in Table 4). For this particular case, it's better to allow for continous changes in selectivity than to assume fixed values.

Similar results were also obtained in the case where true selectivity changes annually (as a function of the relative cohort abundance). However, the difference between assuming block selectivity and fixed selectivity resulted in negligble differences in the ΔAIC values. Moreover, the RMSE for the age-composition data was greater than the true values used to generate the observation errors in age-sampling in models (a) and (b). For model (c), the RMSE was less than the true value for the commercial age-composition, and in model (d) it was identical to the true value.

Retrospective performance

Two useful graphical tools for examining retrspective problems in stock assessment model are referred to here as spagetti plots (Figure 2), and squid plots (Figure 3), respectively. In the spagetti plots, successive estimates of spawning stock biomass based on sequentially removing the terminal year of data are overlayed on each panel. In addition to the estimated spawning biomass in Fig. 2, the true spawning biomass that was used to generate simulated data is also shown for reference. In the squid plots, successive biases of estimated spawning biomass relative to the true spawning biomass based on sequentially removing the terminal year of data are overlaid. In Fig. 3 the percent bias is shown as the $\ln_2(B_t) - \ln_2(\hat{B}_t)$; hence a 100% bias implies that the stock size is over-estimated by a factor of 2.

For the simulated data based on fixed selectivity, retrospective bias was similar in the assessment model for all four alternative selectivity scenarios (Figure 2, 1a, ..., 1d). The maximum retrospective bias observed was roughly 30% over the true spawning biomass (Figure

8

3). The worst performing models were the cases with continuous changes in selectivity over time (1c and 1d).

For cases based on simulated data with discrete time blocks in selectivity, the least amount of bias was observed in the case where the correct model was specified (Figure 3, 2b). Assuming fixed selectivity or continuous changes in selectivity resulted in significantly more retrospecitve bias. Assuming fixed selectivity also resulted in further departures from the true spawning biomass in the initial years.

In the cases where the true selectivity varies over time, the retrospective performance was least biased for the models that assume time-varying selectivity (Figure 3, 3c and 3d). Retrospective peformance is much worse if the selectivity is assumed to be constant, or change in a series of blocks, when the real underlying process is continuous change in selectivity (Figure 3, 3a and 3b).
